PREVENTION, detection, and therapy of myocardial infarction have been fundamental goals of perioperative medicine for many years. As one of the first monitors dedicated to detecting myocardial ischemia, continuous electrocardiography for patients undergoing surgery became more commonly used in the 1950s. Indeed, by 1978, guidelines recommended routine baseline electrocardiogram testing for all adult patients before undergoing surgery.1 However, given that preoperative electrocardiographic abnormalities are not necessarily predicative of postoperative myocardial infarction,2 current practice advisories recognize that preoperative testing should rather be considered for patients with cardiovascular risk factors.3 Intraoperative echocardiography is routinely used for diagnosis and therapy in cardiac surgery.4,5 In addition, it can also be used safely in noncardiac surgery for the detection of new regional wall motion abnormalities indicative of myocardial ischemia.6,7 However, given the resources required for a complete diagnostic echocardiographic examination, its use as a screening tool for myocardial injury in noncardiac surgery is likely limited. A common test used for the diagnosis of perioperative myocardial injury is the measurement of plasma troponin levels. In the past, minor increases in serum troponin levels have often clinically been dismissed as less relevant cases of supply/demand mismatch. This is likely related to the fact that a troponin increase itself does not meet definition criteria for myocardial infarction and a lack of consensus on the most appropriate therapeutic approach. Although it seems intuitive that myocardial infarction leading to cell death is of greater consequence than myocardial ischemia without necrosis, the relevance of minor myocardial injury is not well defined. Furthermore, the progression from reversible ischemic damage to necrosis occurs on a biologic continuum, making cutoffs based on the presumed degree of cellular injury impractical at best. Defining clinical relevance of biomarkers such as Troponin T (TnT) according to their association with meaningful outcomes, such as 30-day mortality, adds substantial value for the practicing clinician. The significance of creatine muscle and brain isoenzyme and TnT to predict mortality and major cardiovascular events has previously been highlighted in a meta-analysis.8

The current study by the VISION Writing Group9 underlines the fundamental importance of even subtle perioperative TnT increases for morbidity and mortality in surgical patients. The current findings are a post hoc analysis of prospectively collected data from The Vascular events In noncardiac Surgery patients eOhort evaluatioN trial.10 The reported analyses extend the interpretation of the The Vascular events In noncardiac Surgery patients eOhort evaluatioN study, as they confirm the independent association of a TnT value of 0.03 ng/ml or greater with all-cause 30-day mortality after adjusting for preoperative risk factors and perioperative events.

In a diverse cohort comprising 15,065 patients with age 45 years or older undergoing noncardiac surgery requiring at least overnight hospitalization, the authors observed a 30-day mortality rate of 1.7%. This is consistent with previously reported death rates within 30 days of surgery. In fact, the magnitude...
of all-cause perioperative mortality would make it the number three cause of death in the United States (fig. 1). The current study suggests that this staggeringly high rate of death after surgery is in many circumstances preceded by often subclinical myocardial injury. The authors used regression analysis to validate a cutoff value for TnT of 0.03 ng/ml or greater to define myocardial injury after noncardiac surgery. Moreover, they discovered that of the 8% of patients who developed myocardial injury after noncardiac surgery, 58.2% would not have fulfilled the universal definition for myocardial infarction. By using data from the 8,351 patients included in the PeriOperative Ischemic Evaluation trial, Devereaux et al. previously reported a mortality rate of 11.6% in patients affected by perioperative myocardial infarction. Even when applying less rigorous criteria for myocardial injury such as a peak TnT value of 0.03 ng/ml, the current study found affected patients to be 4.3 times as likely to die within 30 days. Furthermore, 1 of 10 patients with myocardial injury after noncardiac surgery did not survive 30 days after surgery. The combination of the high incidence of myocardial injury after noncardiac surgery, its prognostic relevance for 30-day mortality, and the ease and feasibility of the test to detect it (using TnT) point to tremendous opportunities for design of clinical studies to test novel interventions to attenuate myocardial injury and perioperative mortality.

Although the need for new cardio-protective therapies has been convincingly demonstrated, causality of myocardial injury and mortality has not. Perioperative ischemia and inflammation are likely to lead to injury in other organs too. Similar to low-level myocardial injury, hypoxia-sensitive tissues such as kidney are also prone to ischemic damage. Although preoperative estimated glomerular filtration rate was not associated with mortality in the current study, it seems conceivable that more sensitive markers of renal injury, such as insulin-like growth factor-binding protein 7 or tissue inhibitor of metalloproteinases-2, could have shown a comparable response pattern to TnT. Hence, the observed mortality could have been due to multiorgan injury rather than isolated myocardial injury. Therefore, interventional clinical trials focused solely on prevention of myocardial infarction might not be successful. Clearly, the development of innovative, mechanism-based approaches to prevent or treat perioperative organ injury, including myocardial injury, is paramount. These will then need to be tested in rigorous clinical trials to translate the results of this study into improved patient outcomes.

Anesthesiology Reflections from the Wood Library-Museum

Longnecker’s Trade Card against the “Asphyxie” of “The Old Way”

In decrying “The Old Way” of nearly asphyxiating patients with brief administrations of 100% nitrous oxide, dentist F. C. Longnecker advertised images of a patient before and after receiving laughing gas via a mouthpiece from a large bag (above). According to Dr. Longnecker:

*With your fingers your nose compress,*

*The real natural place of breath,*

*Then by swallowing, you will see*

*The cause of so much “asphyxie” [sic]*

*Now laid to my pure gas*

*With this nose compress and thermometer too,*

*You will always know how much will do.*
