Effect of Nitrous Oxide on Neuronal Damage and Extracellular Glutamate Concentration as a Function of Mild, Moderate, or Severe Ischemia in Halothane-anesthetized Gerbils

Hideki Taninishi, M.D.,* Yoshimasa Takeda, M.D., Ph.D.,† Motomu Kobayashi, M.D., Ph.D.,‡ Toshihiro Sasaki, M.D.,* Minako Arai, M.D.,* Kiyoshi Morita, M.D., Ph.D.§

Background: The effect of nitrous oxide on ischemic neuronal damage was quantitatively evaluated by use of logistic regression curves.

Methods: Seventy-two gerbils were anesthetized with 1% halothane and randomly assigned to receive 70% nitrous oxide or 70% nitrogen. Forebrain ischemia was performed for 3, 5, or 7 min, and direct-current potential in the hippocampal CA1 region was recorded. Histologic outcome was evaluated 5 days later. Relations of neuronal damage with ischemic duration and duration of ischemic depolarization were determined by logistic regression curves. In some animals, extracellular glutamate concentration was measured every 60 s during forebrain ischemia.

Results: Nitrous oxide increased neuronal damage only with 5 min of ischemia (nitrous oxide vs. nitrogen: 78.5 ± 23.0 vs. 37.3 ± 12.2%, P < 0.01). The percentages of neuronal damage with 3 and 7 min of ischemia were not different with or without nitrous oxide. Logistic regression curves indicated that nitrous oxide significantly increased neuronal damage during the period from 3.07 to 6.63 min of ischemia. Logistic regression curves also indicated that nitrous oxide increased neuronal damage in the condition of the same duration of ischemic depolarization. Nitrous oxide shortened the ischemic duration necessary for causing 50% neuronal damage by 0.82 min. Dynamic change in extracellular glutamate concentration was not different (mean maximum dialysate glutamate concentration: 4.29 ± 3.09 vs. 4.63 ± 1.83 μM).

Conclusion: Administration of nitrous oxide caused an increase in ischemic neuronal damage, but a significant adverse effect was observed with a limited range of ischemic intervals.

Nitrous oxide has been used in general anesthesia for more than 150 yr. Nitrous oxide can provide a certain level of intraoperative analgesia and stabilization of arterial blood pressure, and the low value of blood gas partition coefficient of nitrous oxide enables rapid recovery and early postoperative neurologic assessment.1

Although several studies had been conducted, a definite conclusion regarding the effect of nitrous oxide on ischemic neuronal damage has not been obtained. Baughman et al.2 reported that nitrous oxide attenuated the neuroprotective effect of isoflurane in rats, and Hartz et al.3 reported that nitrous oxide shortened the survival time in mice. On the other hand, Warner et al.4 and Yokoo et al.5 reported that nitrous oxide did not affect the neurologic and histologic outcomes in rats, and David et al.6 reported that administration of nitrous oxide immediately after ischemia for 3 h reduced neuronal damage in rats.

Reduction of cerebral blood flow during ischemia impairs the delivery of oxygen and glucose. With the depletion of oxygen and glucose, membrane potential is lost and neuronal cells are depolarized. Excitatory amino acids (especially glutamate) are then released from the presynaptic folliculus into the extracellular space, and reuptake of excitatory amino acids is also inhibited by the loss of sodium gradient across the cell membrane. Increase in extracellular glutamate activates ionotropic and metabotropic glutamate receptors. As a consequence, calcium ions flow into the postsynaptic neurons, triggering the irreversible process leading to neuronal damage.7,8 It is known that onset time of ischemic depolarization and duration of ischemic depolarization affect the degree of neuronal damage,9,10 and ischemia-induced increase in extracellular glutamate concentration contributes to excitotoxic neuronal damage.11 However, to the best of our knowledge, the effects of nitrous oxide during cerebral ischemia on ischemic depolarization and extracellular glutamate concentration have not been investigated.

Therefore, in the current study, the effects of nitrous oxide at a clinically relevant concentration on ischemic neuronal damage were quantitatively evaluated. For this purpose, cerebral ischemia of three intensities was performed in the same ischemia model, and relations of neuronal damage with ischemic duration and duration of ischemic depolarization were determined by use of logistic regression curves. At the same time, ischemic duration necessary for causing 50% neuronal damage was determined. Furthermore, the effect of nitrous oxide on dynamic change in extracellular glutamate concentration during cerebral ischemia was determined.

Materials and Methods

Animals
A total of 72 male Mongolian gerbils (Charles River Japan, Yokohama, Japan) weighing 70.6 ± 5.2 g were used. The animals had free access to water and were fed ad libitum before the experiments. All experiments were performed in accordance with the National Institutes of Health animal care guidelines and were approved by the Animal Research Control Committee of Okayama University Medical School, Okayama City, Okayama, Japan.

Evaluation of the Relations of Neuronal Damage with Ischemic Duration and Duration of Ischemic Depolarization
Forty-eight male Mongolian gerbils were used in this experiment. The animals were randomly assigned to a group receiving nitrous oxide (nitrous oxide group, n = 24) and a group receiving nitrogen (nitrogen group, n = 24). Anesthesia was induced with 4% halothane in oxygen and maintained with 1% halothane in 30% oxygen balanced with 70% nitrous oxide (nitrous oxide group) or 70% nitrogen (nitrogen group) under spontaneous ventilation. Because minimum alveolar concentration (MAC) of halothane has been reported to range between 0.88 and 1.26 vol% in rodents,12–14 1% halothane was balanced with 70% nitrous oxide (nitrous oxide group) or 70% nitrogen (nitrogen group) under spontaneous ventilation. Because minimum alveolar concentration (MAC) of halothane has been reported to range between 0.88 and 1.26 vol% in rodents,12–14 1% halothane was considered to be approximately 1 MAC in the current study. Bilateral common carotid arteries were exposed, and a silicon tube for initiation of ischemia (0.3 mm in diameter) was placed around each of these arteries. After head placement in a stereotaxic apparatus (Narishige, Tokyo, Japan), an electroencephalogram was monitored with needle electrodes placed subcutaneously in the left frontal region. After making bar holes in bilateral temporal bones, two borosilicate glass electrodes (tip diameter of <5 μm) were placed in the bilateral hippocampal CA1 regions according to the brain atlas (2 mm posterior to the bregma, 1.5 mm bilateral from the sagittal line, and 1 mm below the cortical surface). A laser-Doppler flow probe (ALF 2100; Advance, Tokyo, Japan) was placed on the surface of the right temporal bone for continuous monitoring of regional cerebral blood flow.

After a 30-min stabilization period after surgical preparation, forebrain ischemia was initiated by occlusion of bilateral common carotid arteries with plumbs (each weighing 4 g) for 3, 5, or 7 min (n = 8 in the two groups for each duration). The ischemia and reperfusion were confirmed by the sudden decrease and rapid increase in regional cerebral blood flow on a laser-Doppler flow meter. Changes in direct-current (DC) potentials, electroencephalograms, and regional cerebral blood flow were recorded and analyzed using an analog–digital system (Axo-Scope and Digidata 1200 B; Axon Instruments, Foster, CA) from 5 min before the ischemia to 45 min after the initiation of ischemia. Changes in DC potentials were assessed by measuring onset time (from the initiation of ischemia to a sudden negative shift of DC potential), recovery time (from the initiation of recirculation to 80% recovery from maximal DC deflection), and duration of ischemic depolarization (from the start of the sudden negative shift of DC potential to 80% recovery from maximal DC deflection). Because Dirnagl et al.16 reported that data obtained by using a laser-Doppler flow meter only provide accurate information on change in regional cerebral blood flow, the percent change in regional cerebral blood flow was expressed in the current study.

During the observation period, administration of nitrous oxide or nitrogen was continued. Brain surface temperature was maintained at 37.0°C ± 0.5°C with a gentle flow of warmed saline (38.0°C ± 0.5°C, monitored and controlled) into a polyethylene cylinder (5 mm in height, 13 mm in ID) placed on the skull surface. Rectal temperature was maintained with a heated-water blanket and an infrared lamp at 37.0°C ± 0.5°C. Because Kuroiwa et al.17 reported that the possibility of neuronal death caused by postischemic hyperthermia could be excluded by maintenance of normothermia after 85 min after reperfusion, brain surface and rectal temperatures were controlled from 30 min before the ischemia to 90 min after the reperfusion.

After a 5-day survival period, all animals were anesthetized with 4% halothane in oxygen and perfused with heparinized physiologic saline (20 U/ml) and 6% paraformaldehyde in 0.1 M phosphate buffer (pH 7.4). The areas in which DC potential had been recorded were marked by using a 27-gauge needle with blue ink on the tip of the needle before enucleating the brains. After brain removal and paraffin embedding, tissue including the bilateral hippocampal CA1 regions (the area marked with blue ink) was sectioned coronally (5 μm in thickness). The sections were stained with hematoxylin and cosin. The number of injured pyramidal neurons in the bilateral hippocampal CA1 regions was counted by an observer who was blinded to this study. The areas in which DC potential had been recorded were identified by finding the ink spot or the mark made with the needle with 40-power magnification. The area was enlarged to 400-power magnification, and the numbers of both damaged and intact pyramidal neurons in bilateral hippocampal CA1 regions were counted. The percentages of neuronal damage in the two groups were calculated as damaged neurons/total neurons × 100 in the visual field. In the current study, pyramidal neurons showing aggregated chromat in the nucleus, shrinkage, or eosinophilic staining in the cytoplasm were considered to be injured.

Dose–reaction curves evaluating acute drug toxicity in toxicology are usually expressed by the use of probit curves. In the current study, the relations of neuronal damage with isch amic duration and duration of ischemic
depolarization were determined by logistic regression curves (probit curves) as dose–reaction curves. Ischemic duration or duration of ischemic depolarization was represented on the x-axis, and neuronal damage was represented on the y-axis. The y-axis was converted to probit transformation, and regression lines in the two groups were drawn. At the same time, 95% confidence intervals were also drawn. Finally, the y-axis was returned to percent change. These regression curves were drawn by using data-analysis software (Origin Pro 7.5; OriginLab Corporation, Northampton, MA). A probit curve, which expresses the probability of occurrence, is used to search for the median lethal dose in toxicology. Therefore, in this study, ischemic durations necessary for causing 50% neuronal damage ($P_{50}$-ischemia) in both groups were determined from logistic regression curves.

Because bleeding during arterial catheterization or blood sampling (100 μl) decreased arterial pressure in gerbils and it may affect the neuronal damage after forebrain ischemia, we evaluated physiologic variables in another set of animals. Ten animals were randomly assigned to a group receiving nitrous oxide (nitrous oxide group, n = 5) or a group receiving nitrogen (nitrogen group, n = 5). A polyethylene catheter (PE-10; IMI, Tokyo, Japan) was inserted into the right femoral artery for continuous monitoring of mean arterial pressure. Bilateral common carotid arteries were exposed, and a silicon tube for initiation of ischemia was placed around each of these arteries. After head placement in a stereotaxic apparatus, 5 min of forebrain ischemia was performed by the same procedure as that used for the measurement of DC potential. Mean arterial blood pressure was recorded and analyzed using an analog–digital system (Axo-Scope and Digidata 1200 B) from 5 min before the ischemia to 20 min after the initiation of ischemia. Arterial blood gas analysis (pH, arterial oxygen tension, arterial carbon dioxide tension, hydrogen carbonate ions, blood glucose, and hematocrit) was performed before the ischemia (i-STAT; Fuso, Osaka, Japan).

**Statistical Analyses.** All values are expressed as mean ± SD. Data for physiologic values and onset time were analyzed by Student $t$ test. The changes in cerebral blood flow on a laser-Doppler flowmeter and mean arterial blood pressure were analyzed by two-way analysis of variance (groups vs. time). Other values were analyzed with analysis of variance followed by Scheffé test for multiple comparisons. A level of $P < 0.05$ was considered to be significant in all statistical tests.

**Measurement of Dynamic Changes in Extracellular Glutamate Concentration**

Fourteen male Mongolian gerbils were used in this experiment. The animals were randomly assigned to a group receiving nitrous oxide (nitrous oxide group, n = 7) or a group receiving nitrogen (nitrogen group, n = 7). Concentrations of oxygen, nitrous oxide or nitrogen, and halothane were the same as those in the first experiment. The preparative surgery until head placement was also the same as that in the first experiment. After making a bar hole in the right temporal bone, a microdialysis probe (membrane length of 1.5 mm, molecular weight cutoff of 50,000, OD of 220 μm; A1-015, Eicom, Kyoto, Japan) was inserted instead of the borosilicate glass electrode in the area that mostly reflected the right hippocampal CA1 region (2 mm posterior to the bregma, 1.5 mm lateral from the sagittal line, and 2 mm below the cortical surface). Before the experiment, the relative recovery rate of each probe was determined by performing microdialysis in a glutamate standard solution (100 μM). The probes were perfused with Ringer’s solution at 2 μl/min using an infusion pump (ESP-32; Eicom). The bias of increase in extracellular glutamate concentration caused by mechanical injury during probe insertion disappeared within 30 min. Therefore, after a 60-min stabilization period after the microdialysis probe insertion, 5 min of forebrain ischemia was performed by the same procedure as that used in the first experiment. The dialysate was automatically collected every 60 s using a fraction collector (EFC-82; Eicom) from 5 min before to 30 min after the reperfusion.

Quantification of glutamate was performed by high-power liquid chromatography with computerized control (Nanospace Syscon 21; Shiseido, Tokyo, Japan). Because such a small amount of sample (2 μl each) cannot be injected into the chromatography column, collected dialysates were diluted by adding Ringer’s solution (4 μl each). Diluted solutions (each 5 μl) were used to separate glutamate using an isolation column (4.6 × 150 mm, GU-GEL; Eicom). Isolated glutamate was converted to hydrogen peroxide by glutamate oxidase packed in an enzyme immobilized column (E-ENZYMPC; Eicom). For electrochemical detection, oxidative potential was applied to a platinum electrode at 450 mV versus an Ag/AgCl reference electrode. The mobile phase (50 mM ammonium chloride) was pumped with a microvolume plunger system (Nanospace SI-2 3001; Shiseido) at a rate of 400 μl/min. Corrected maximum extracellular glutamate concentration was calculated from the dialysate glutamate concentrations divided by relative recovery rate of each probe.

During the experimental period, administration of nitrous oxide or nitrogen was continued. Brain surface and rectal temperatures were maintained at 37.0° ± 0.5°C as done in the first experiment from 30 min before the ischemia to the end of the experiment.

**Statistical Analyses.** Values are expressed as mean ± SD. Statistic differences were evaluated by two-way analysis of variance (groups vs. time). To determine whether ischemia had any effect on the glutamate concentration, paired $t$ tests were used to compare basal (5 min before the ischemia) versus peak glutamate concentrations in the two groups. Results

All animals in the two groups in which forebrain ischemia was performed for 3, 5, or 7 min were able to maintain their position symmetrically, walk, and eat food after the ischemia, and they all survived for 5 days after the ischemia.

Results of arterial blood gas analysis are shown in table 1. Blood glucose values in the two groups were higher than the normal range, and other values were within the normal ranges. There were no significant differences between the nitrous oxide group and nitrogen group.

The changes in mean arterial pressure (table 1) and regional cerebral blood flow determined by a laser-Doppler flowmeter (rate of changes from the values before ischemia = 100; table 2) were not significantly different between the nitrous oxide group and nitrogen group. The data of electroencephalogram and power amplitude of electroencephalogram are shown in figure 1. There was no significant difference between the two groups with any frequency with multiple comparisons.

ischemia was 0.91. The percentages of neuronal damage with 3 and 7 min of ischemia were not different in the two groups.

The relations between ischemic duration and neuronal damage are shown in figure 2. The logistic regression curves indicated that the percentage of neuronal damage in the nitrous oxide group was higher in the condition of the same ischemic duration (nitrous oxide group: 4.45 vs. nitrogen group: 5.27). The 95% confidence intervals did not overlap from 3.07 to 6.63 min of ischemic duration (P < 0.0001). The percentages of neuronal damage needed to cause 50% neuronal damage in the nitrous oxide group and nitrogen group were 4.45 and 5.27 min, respectively.

Fig. 2. Relations between ischemic duration and neuronal damage in all experimental animals. Rectangles and circles represent data for animals in the nitrous oxide group and nitrogen group, respectively. The logistic regression curves show close relations between ischemic duration and neuronal damage in the nitrous oxide group (line A: r² = 0.59, P < 0.0001; nitrogen group, line B: r² = 0.91, P < 0.0001). The 95% confidence intervals (shaded areas) did not overlap from 3.07 to 6.63 min of ischemic duration. Ischemic durations necessary for causing 50% neuronal damage in the nitrous oxide group and nitrogen group were 4.45 and 5.27 min, respectively.

Fig. 3. Relations between duration of ischemic depolarization and neuronal damage. Rectangles and circles represent data for animals in the nitrous oxide group and nitrogen group, respectively. The logistic regression curves show close relations between duration of ischemic depolarization and neuronal damage in the nitrous oxide group (line A: r² = 0.64, P < 0.0001; nitrogen group, line B: r² = 0.78, P < 0.0001). The 95% confidence intervals (shaded areas) did not overlap from 4.96 to 8.44 min of duration of ischemic depolarization.

Discussion

In the current study, administration of nitrous oxide increased neuronal damage in the hippocampal CA1 region only with 5 min of ischemia. Logistic regression curves indicated that nitrous oxide increased neuronal damage in the condition of the same ischemic duration and shortened the ischemic duration necessary for causing 50% neuronal damage (P₅₀ ischemia) from 5.27 to 4.45 min.

As mentioned in the introduction, results of past studies on the effect of nitrous oxide on ischemic neuronal damage have not been consistent. In past studies, various methods for initiation of cerebral ischemia (anoxia, right carotid occlusion with hemorrhage, middle cerebral arterial occlusion) were used. Furthermore, ischemia of only one intensity (ischemic duration rang-
6 min. Dynamic changes in extracellular glutamate concentration were not significantly different in the two groups (investigated P50-ischemia values for hypothermia (34°C) and thiopental, respectively. They found that the values of P50-ischemia were extended by 3.2 min (hypothermia) and 3.3 min (thiopental) compared with the value for halothane. The difference was 0.28 min, suggesting that the cascade of neuronal damage7,8 began slightly earlier by nitrous oxide. One of the factors that have been shown to affect onset time of ischemic depolarization is cerebral metabolic rate,9,20,21 and some studies have shown that nitrous oxide increased cerebral metabolic rate.22,23 Although we do not have any data to show the actual cerebral metabolic rate, the results of the current study suggested that administration of nitrous oxide affects the cerebral metabolic rate.

The logistic regression curves indicated that nitrous oxide increased neuronal damage in the condition of the same duration of ischemic depolarization. For example, when the duration of ischemic depolarization was 6.50 min, the percentages of neuronal damage in the nitrous oxide group and nitrogen group were 50.0% and 66.6%, respectively. This result suggested that some factors after the onset of ischemic depolarization were involved in the increase in neuronal damage. Because extracellular glutamate release is one of major factors occurring early after the onset of ischemic depolarization and because the percentages of neuronal damage in the nitrous oxide group and nitrogen group were significantly different with 5 min of ischemia, extracellular glutamate concentration was determined with 5 min of cerebral ischemia.

To the best of our knowledge, the current study is the first study in which the effect of nitrous oxide on dynamic change in extracellular glutamate concentration was examined in such short intervals (every 60 s) during cerebral ischemia. Sampling dialysate every 60 s enabled detection of a significant difference between the two groups, which would not have been possible due to the equalization of glutamate concentration in the case of long sampling intervals. In both groups, extracellular glutamate concentrations began to increase in one sample earlier or later in the other two animals in the nitrous oxide group. Mean values of glutamate concentrations in the first sample after reperfusion in the nitrous oxide group (4.15 ± 3.05 μM) and nitrogen group (i.e., maximum concentration in the nitrogen group: 4.63 ± 1.83 μM) were significantly (6.0- to 6.7-fold) higher than those of 5 min before ischemia (nitrous oxide group; P = 0.02; nitrogen group; P < 0.01). Glutamate concentrations rapidly decreased and returned to the baseline values within 6 min. Dynamic changes in extracellular glutamate concentration were not significantly different in the two groups (P = 0.75).
glutamate concentration began to increase soon after initiation of ischemia and rapidly decreased immediately after reperfusion. Because DC potentials in both groups repolarized later than 2 min after the reperfusion (i.e., recovery times with 5 min of ischemia in the nitrous oxide group and nitrogen group were 2.97 ± 1.10 and 2.88 ± 0.65 min, respectively; table 3), the beginning of decrease in glutamate concentration was earlier than repolarization. This observation suggested that the decrease in glutamate concentration would be associated with washout of released glutamate by recirculation of cerebral blood flow rather than reuptake of glutamate into astrocyte by repolarization.

Despite the short sampling interval, the dynamic changes in extracellular glutamate concentration in the two groups were not significantly different. After the onset of ischemic depolarization, voltage-dependent calcium channels (mainly N- and L-type calcium channels) are activated, and calcium ions enter into the presynaptic terminal. Presynaptic glutamate is then released into the extracellular space and binds to postsynaptic ionotropic and metabotropic glutamate receptors. These receptors are activated and the activation triggers influx of calcium and sodium into the postsynaptic neuronal cells. Increase in calcium concentration in neuronal cells stimulates further glutamate release. However, nitrous oxide inhibited Ca(v)3.2 of T-type calcium currents and ionotropic glutamate receptor–induced currents. Nitrous oxide does not inhibit metabotropic glutamate receptors.

In addition, Amorim et al. reported that the values of calcium influx during hypoxia were not different with or without nitrous oxide in rat hippocampal slices. Because increase in intracellular calcium concentration correlates with glutamate release, it is likely that administration of nitrous oxide during cerebral ischemia did not change intracellular calcium concentration.

The results of the current study suggested that some factors other than extracellular glutamate concentration after the onset of ischemic depolarization were involved in the increase in neuronal damage by nitrous oxide. Hoffman et al. reported that nitrous oxide increased plasma catecholamine level and decreased neurologic score in a rat model. Pap et al. reported that nitrous oxide (used with fentanyl) increased the value of Bax and decreased the value of Bcl-2 at 1 day and 3 days after ischemia, respectively, accelerating apoptosis in rats. Plasma catecholamine or apoptotic factor might be related to the progression of neuronal damage by nitrous oxide.

Because Kirino et al. reported that the histologic change of pyramidal cells in the hippocampal CA1 region was completed within 4 days after ischemia, the percentage of neuronal damage was assessed at 5 days after ischemia in the current study. In this context, Elsersy et al. reported that the percentages of surviving neurons in a nitrous oxide–fentanyl group was lower than that in the isoflurane group at 5 days after ischemia in a forebrain ischemia and hemorrhage model of rats. They also reported that the percentage of surviving neurons in an isoflurane group and nitrous oxide–fentanyl group were similar at 3 weeks and 3 months after the ischemia, suggesting that the effect of nitrous oxide on ischemic neuronal damage could have changed at more than 3 weeks after the ischemia. The long-term effect of nitrous oxide on cerebral ischemia is not clear from the results of the current study, and further investigation is required to evaluate the long-term outcome in the same model as that used in the current study.

Nitrous oxide alone has low potency, and the MAC of nitrous oxide is 104 vol% in humans and higher (ranging from 155 to 235 vol%) in rodents. Therefore, in many cases, nitrous oxide is administered with other potent anesthetics such as fentanyl, barbiturates, or volatile anesthetics. In the current study, 1% halothane was administered as a basal anesthetic and 70% nitrous oxide was administered as an additional agent. Because deep anesthesia changes physiologic parameters such as blood pressure and carbon dioxide tension, depth of anesthesia may affect ischemic neuronal damage. Although anesthesia in the nitrous oxide group seems to be deeper than that in the nitrogen group, values of arterial blood gas analysis, changes in mean arterial pressure, power amplitudes of electroencephalogram, and changes in regional cerebral blood flow were not significantly different in the two groups. Therefore, the difference in anesthetic depth in the two groups did not change the physiologic parameters that might affect the severity of neuronal damage.

Values of glucose in the two groups were higher than the upper limit of the normal range. As shown in many past studies, peri-ischemic hyperglycemia worsens ischemic neuronal damage. However, there was no difference between blood glucose values in the nitrous oxide group and nitrogen group. Therefore, in the current study, the hyperglycemic state might have caused an increase in overall neuronal damage in the two groups but would not have played a role in the increase in neuronal damage in either the nitrous oxide group or nitrogen group.

In summary, the effect of nitrous oxide on neuronal damage was quantitatively evaluated at 5 days after forebrain ischemia in gerbils. Administration of nitrous oxide increased neuronal damage only with 5 min of ischemia. The percentages of neuronal damage with 3 and 7 min of ischemia were not different with or without nitrous oxide. Logistic regression curves indicated that nitrous oxide significantly increased neuronal damage during the period from 3.07 to 6.65 min of ischemia and shortened P50-ischemia by 0.82 min. Therefore, administration of nitrous oxide caused an increase in ischemic neuronal damage, but a significant adverse effect was observed with a limited range of ischemic intervals.
Furthermore, nitrous oxide did not affect dynamic change in extracellular glutamate concentration during cerebral ischemia, suggesting that unknown factors other than extracellular glutamate concentration after the onset of ischemic depolarization might be involved in the increase in neuronal damage caused by nitrous oxide.
