In Reply:—Tanaka et al.1 introduce an additional, intriguing factor (with an historical past) in the search for the explanation as to why phenylephrine might be associated with such a high incidence of transient neurologic symptoms (TNS). The subsequent comments by Sakura et al.2 put this concern about sodium bisulfite into sharp perspective—a critical step that helps us maintain an appreciation for the clinical relevance of the actual doses of sodium bisulfite given and one that discourages us from unduly focusing on just one potential contributor.

Lambert3 voices the anticipated reaction to the rhetorical emphasis of the Editorial View.4 The valid question posed is, is tetracaine a safer anesthetic (whether it increases blood flow or not)? He provides the reasonable opinion that the answer is no. Further, we learn that commonly used local anesthetics share the potential for neurotoxicity. This is an important reality, especially as we consider the contemporary manifestations thereof through TNS.

Blood Loss from a Defective Needleless Arterial Sampling Port

To the Editor—To decrease the risk of needle sticks, our institution uses a closed system for sampling of arterial blood (Triple Line SafeSet Kit #46076-27, Abbott Laboratories, Chicago, IL). At the sampling port, a thick rubber cap with a built-in slit is penetrated with a blunt needle. Recently we had a case in which flushing of the arterial tubing resulted in dislodgment of the rubber cap from the sampling port. This led to an open arterial line with bleeding and loss of the arterial trace. Attempts to plug off the hole were unsuccessful because standard Luer-lock caps are too small for the size of the resulting defect. In this patient, the arm in which the arterial catheter had been placed was tucked at his side and was not readily accessible. We stopped the bleeding by covering the open port with a sterile transparent dressing (Tegaderm, 3M company, St. Paul, MN). A silk string was wrapped around the sides of the dressing to prevent the arterial pressure from displacing it. This restored the arterial tracing, but the sampling port could not be used, and subsequent arterial samples had to be taken at the transducer site. At the end of the procedure, the arterial line system was replaced with a new one. Inspection of the malfunctioning sampling port revealed that the plastic housing had not been molded over the rubber cap (fig. 1). Without the molding, there is nothing to hold the rubber cap, and it can easily be displaced during flushing.

We estimated the blood loss caused by the defective sampling port at approximately 20 cc. However, the system we were using had an identical sampling port close to the insertion site. If the defect had

been on that sampling port, the blood loss would not have been immediately apparent because it was covered by surgical drapes, and larger amounts of blood would have been lost. We have contacted the manufacturer and informed them of this defect so that hopefully this type of problem can be avoided in the future.

Peripherally Administered NSAIDs Provide for Patient Benefit

To the Editor: — We read with interest the excellent review article by Callesen and Kehlet regarding pain after hernia repair. The authors conclude that intrawound nonsteroidal anti-inflammatory drugs (NSAIDs) have not been shown to have been beneficial in patients having herniorrhaphy.

We would like to cite our recently published article in which we studied patients undergoing inguinal hernia repair during local anesthesia. The patients were randomized to receive ketorolac either intravenously or in the surgical wound. We were able to demonstrate an increased time to first analgesics, a decreased oral analgesic requirement, and lower 24-h movement-associated pain scores in the surgical site group.

We believe that our data, taken in concert with our studies in patients undergoing arthroscopy, provide evidence that peripherally administered NSAIDs provide for patient benefit.

Unusual Cause of Intravenous Catheter Obstruction

To the Editor:—Intravenous catheters occasionally obstruct because of blood clots or kinking of the catheter. We experienced a case of intravenous catheter obstruction caused by a cored fragment of a medication vial stopper.

A patient had a 20-gauge, 1-inch intravenous catheter placed in the dorsum of the hand. An intravenous induction of anesthesia was uneventful. Thirty minutes into the procedure (near the end of the surgery), observation of the drip chamber showed that the gravity-driven infusion had ceased. All attempts at restarting the infusion by gentle aspiration or flushing solution through the ports failed. When the intravenous catheter was later removed, a small gray fragment was seen occluding the catheter. The fragment was removed from the catheter. It was roughly spherical, measured about 1 mm in diameter, and was similar in consistency and color to the stopper of the succinylcholine used during induction of anesthesia.

We believe that the fragment was a small piece of the stopper of
